**Abstract:** Software Defined Network (SDN) offers convenience in managing network devices by simply setting the software control plane so as to reduce the complexity of network configuration. However, the ease of management offered is not always accompanied by an increase in network performance when compared to conventional network architectures. This study will perform a performance comparison analysis between networks with SDN architecture (OpenFlow) and conventional architecture. The research methods applied are: topology implementation on Mininet, network simulation and data collection, data analysis, and comparative analysis. Network performance testing is carried out based on latency parameters that are simulated in one subnet using the Mininet emulator. From the results of the latency test, it is found that the average latency on the SDN network is 0.119ms, while the average latency on the conventional network is 0.09588ms. Based on these results, it can be concluded that the network topology that has better performance based on latency parameters is a conventional network topology with an average latency value of 0.09588ms.

Keywords: Control plane; Latency; Mininet; Network; SDN;

### **INTRODUCTION**

Software Define Networking (SDN) is a new approach to designing, building and managing computer networks by separating the control plane and data plane which is different from conventional network networks where the control plane and data plane are still combined.

The main concept of SDN is network centralization where, where all the settings are in the control plane, especially on the data plane platform that uses an abstraction layer for all network devices on the SDN architecture. So that it is easy to manage network devices by simply setting the control plane software and is able to reduce the complexity of network configuration. The most prominent protocol on SDN is Openflow (Ummah, 2016).

Openflow became the first standard as an interface in communication between the forwarding plane and control plane in SDN architecture where Openflow can configure network devices and choose the optimal path for traffic applications and controllers that allow software to run on various types of hardware (Anam & Adrian, 2017). However, the advantages offered by the SDN network are not necessarily followed by an increase in performance when compared to conventional networks.

Research related to this topic has been reviewed by a number of previous researchers. Research conducted to compare the performance of SDN with conventional networks based on the parameters of jitter, delay, and throughput showed that SDN had better delay, jitter, and throughput results (Hernandez, Jimenez, Pranolo, & Rios, 2019). In another study, it was found that, by analyzing key network metrics including round-trip-time (RTT) and data transfer rate (DTR), the results show that the location of the controller has a demonstrable effect on network performance (Banjar, Pupatwibul, Braun, & Moulton, 2014). The SDN network has Quality of Services (QoS) results compared to conventional networks and the latency value produced by SDN is between 0.019 - 0.084ms (Nugroho, Irfan, & Faruq, 2019).

Based on the background that has been described, this study aims to perform a comparative analysis of the performance of the SDN network compared to conventional networks with latency parameters. The formulation of the problem in this research is between SDN and Conventional, which network topology is better and what are the results obtained.

## LITERATURE REVIEW

Software Defined networking (SDN) is a computer networking approach that allows network administrators to dynamically program, control, modify, and manage network behavior through open interfaces and low-level functional abstractions. SDN is intended to address the fact that traditional networked static architectures do not support the dynamic and scalable compute and storage needs of modern computing environments such as data centers. This is done by separating the system that makes decisions about where the traffic is sent from the system that underlies the traffic to the chosen destination (Haleplidis et al., 2015). The advantages and conveniences offered by the SDN architecture are not necessarily followed by an increase in network performance when compared to conventional network architectures that use the TCP/IP protocol. SDN is commonly associated with the Openflow protocol (for remote communication with network plane elements to determine the path of network packets across network switches) since its second appearance in 2011 (Eissa, Bozed, & Younis, 2019).

Openflow is a protocol that functions in bridging communication between the Data plane Layer (routers, openflow switches) and the Control plane Layer (Controller) on the SDN architecture. Openflow allows direct access and manipulation of the data plane (routers, openflow switches). Openflow based on SDN architecture requires configuration of network devices every time, service policies can change, so as to reduce network configuration errors and inconsistent policies (Heryanto & Afrilia, 2016). In addition, openflow allows switches from different vendors - often each with their own proprietary interface and scripting language - to be managed remotely using a single open protocol. The inventors of the protocol considered openflow as an enabler of the software-defined SDN network (IEEE, 2017).

QoS is a technique for managing bandwidth, delay, jitter, and packet loss for flows in a network. The purpose of the QoS mechanism is to influence at least one of the four basic QoS parameters that have been determined. Meanwhile, according to Ningsih et al, Quality of Service is the ability of a network to provide better services for traffic services that pass through it. QoS is an end-to-end architectural system and is not a feature of the network. The purpose of QoS is to meet the needs of different services, which use the same infrastructure (Iskandar & Hidayat, 2015).

Latency is the time it takes for data to travel the distance from origin to destination. Latency can be affected by distance, physical media, congestion or also long processing times (Gallenmüller, Naab, Adam, & Carle, 2020). Latency is divided into several categories as follows (ETSI, 2018):

Table 1. Latency Category			
Latency Category	Delay Quantity		
Very Good	<150ms		
Good	150 s/d 300ms		
Medium	300 s/d 450ms		
Bad	>450ms		

Average latency =  $\frac{Total \ Latency}{Total \ packages \ received}$  (1)

#### **METHOD**

This research was carried out from November 2021 to February 2022. The research location was carried out at the Computer Network Laboratory, Labuhanbatu University. The data source is obtained from the simulation results of SDN and Conventional networks using mininet which is repeated 25 times for each network topology. Figure 1 is an illustration of the research stages.

Fig. 1 Research Stages

The system built in this research is based on a simulation using a Mininet emulator. For SDN architecture, the controller will be connected directly to the Mininet emulator which consists of two interconnected OpenFlow switches. Each OpenFlow switch will be connected to two hosts respectively. As for the conventional architecture, the Controller is not used. The scope of the system represents the network that is still in 1 subnet.

# RESULT

In the test, measurements of latency were carried out by sending ICMP packets by paying attention to changes in packet size, namely 64, 128, 512, 1024, 2048, and 4096 bytes. The test is carried out using the ping tool with the command scheme given in Figure 4. In this scheme, an interval size of 10 is used with a total packet that is generated randomly. As for the packet size, it depends on the size of the ICMP packet to be sent.

Fig. 5 Conventional Architecture Latency Test

From the results of the tests carried out, the latency test values for SDN and conventional architectures are presented in the graph in Figure 6.

Fig. 6 Latency Test Results

From these results, it is known that the best latency value for SDN and conventional network architectures is obtained when the ICMP packet size is 128 bytes. This is because at the size of 128 bytes the smallest latency value is obtained following the formula (1).

# DISCUSSIONS

Tests by transmitting ICMP packets which aim to measure the latency value for both network architectures, show that there is a significant additional latency value for the SDN architecture. This is because the communication between the switch and the controller in handling packets to be sent or received. If a comparison is made between the two architectures, the results show that the conventional architecture is still better than the SDN architecture with an average delay value of 0.09588. This is because in the SDN architecture every decision to transmit packets is made by the controller. This is because if the first echo request packet requires more time

for the address resolution process by the Controller and at the same time the Controller enters flow entries into the flow tables of the switch so that the next packet forwarding does not require the resolving address process again.

The high latency value caused by communication between controllers and switches occurs in 2 stages, namely packet arrival and forwarding table updates. In the first stage, when receiving the first ICMP packet. The switch sends a packet\_in message to the Controller containing the metadata and the first 128B of the packet. In the second stage, the controller sends a flow\_mods message to enter or update flow entries into the flow tables of the switch. This stage is called inbound and outbound latency. As the test results show that the first ICMP packet of each packet size sent always shows a very large latency value for the SDN network architecture.

### CONCLUSION

Based on the results of research and network performance testing of SDN and conventional network architectures that have been carried out, it can be concluded that a better network topology based on latency parameters is a conventional network topology with an average latency value of 0.09588ms.

Some suggestions that can be considered for future research are, testing can involve more than one network subnet, using more than two controllers with a more complex network topology.
